Abstract

The land surface emissivity (LSE) in the thermal infrared (TIR) is an essential parameter in the retrieving the land surface temperature (LST) from space. This paper describes the LSE maps in TIR three bands (centered at 10.4, 11.2 and 12.4 µm) used for retrieving the LST from Himawari-8. Himawari-8, a next-generation geostationary satellite has high spatial and temporal resolutions compared to previous geostationary satellites. Due to these improvements, it is expected that the Himawari-8 LST product contribute to observe small-scale environments in high-frequency. In this study, the LSE is estimated by a semi-empirical method, which is a combination of the classification based method and the normalized difference vegetation index (NDVI) thresholds method. The land cover classification information is taken from the Global Land Cover by National Mapping Organizations version3 (GLCNMO 2013). Material emissivities of soil, vegetation and others are taken from the MODIS UCSB emissivity library and the ASTER spectral library. This method is basically following to Peres and DaCamara (2005) but advanced considerations are added. They are phenology of vegetation, flooding of paddy field, snow/ice coverage and the internal reflections (cavity effect) in the urban area. The average cavity effect on LSE in urban canopy is approximately 0.01, but it reaches 0.02 in built-up area. The sensitivity analysis shows that the total LSE

48   errors for three bands are less than 0.02. The LSE estimation is especially stable at the

49   vegetation area, where the error is less than 0.01.

53

1. Introduction

The land surface emissivity (LSE) in the thermal infrared (TIR) is important for the estimation of the land surface temperature (LST) and surface energy budgets. The LST and surface energy budgets are useful for the studies of environmental issues, such as desertification and urban heat islands (Sobrino and Raissouni, 2000; Weng, 2009). The LSE varies depending on various factors, such as the vegetation or soil type, surface roughness and water content. The seasonal change of vegetation also affects the LSE. Even a small LSE estimation error affects the final LST retrieval (Li et al., 2013a). Therefore, it is necessary to consider the various factors affecting the LSE as much as possible. The purpose of this study is to develop the LSE maps in TIR bands used for retrieving the LST from Himawari-8. Himawari-8, the successor to MTSAT-2, was launched in October 2014 and started operational observations in July 2015. This geostationary satellite locates above the equator at longitude 140.7° E and is flying at an altitude of 35786 km. The Advanced Himawari Imager (AHI) onboard Himawari-8 contains three visible bands (band 1, 2 and 3 centered at 0.47, 0.51, and 0.64 µm) and thirteen infrared bands (band 4–16 centered at 0.86, 1.61, 2.25, 3.9, 6.2, 6.9, 7.3, 8.6, 9.6, 10.4, 11.2, 12.4, and 13.3 µm). The spatial resolutions of the visible/near-infrared bands (band 1–4) are 0.5–1.0 km and the infrared bands (band 5–16) are 2.0 km. The observation cycle of the AHI is 2.5 minutes in the area of Japan and 10 minutes for the full disk. The spatial and temporal resolution are

73　both improved compared to the MTSAT-2. Due to these improvements, the Himawari-8

74　LST product is expected to contribute to observe small-scale features in high-frequency

75　compared to GMS and MTSAT series. The spectral range 10–12.5 μm in the window

76　thermal infrared is suitable for retrieving land surface temperature using single or

77　multi-channel algorithm (Li et al., 2013a). The AHI has three TIR bands, bands 13, 14 and

78　15 (centered at 10.4, 11.2 and 12.4μm) in the spectral range of 10–12.5 μm. Therefore, we

79　develop the LSE maps for bands 13, 14 and 15.

80　　Various LSE estimation methods have been proposed for various sensors, which are

81　generally divided into three types (Li et al., 2013b); semi-empirical methods (Snyder et al.,

82　1998; Peres and DaCamara, 2005; Trigo et al., 2008; Sobrino et al., 2008), multi-channel

83　temperature emissivity separation methods (Sobrino et al., 2001; Peres and DaCamara,

84　2004), and physically based methods (Petitcolin, and Zhang, 2000). Each method has its

85　own advantages and limitations. We employ a semi-empirical method, which is a

86　combination of the classification based method and the normalized difference vegetation

87　index (NDVI) thresholds method. This method is basically following to Peres and

88　DaCamara (2005). The classification based method assigns the predetermined LSE value

89　to each pixel based on the use of a land-cover classification information. The NDVI

90　thresholds method estimates the LSE by considering the surface component as being a

91　mixture of bare soil and vegetation. The visible and near-infrared bands of AHI, bands 3, 4

92   and 5 (centered at 0.64, 0.86 and 1.61 μm), enable the estimation of the fraction of

93   vegetation, so that it becomes possible to apply the method proposed by Peres and

94   DaCamara (2005). Figure 1 shows the flowchart of our LSE estimation method. Peres and

95   DaCamara (2005) has used the NDVI thresholds method considering the internal

96   reflections (cavity effect) due to the vegetation canopy, but we attempt to consider the

97   cavity effect due to the urban canopy additionally. Furthermore, we consider the seasonal

98   variation of vegetation and specific variation in the paddy field using Himawari-8 visible and

99   near-infrared reflectances. Section 2 describes the NDVI thresholds method and the

100   assignment method to each land cover type. Section 3 describes the predetermined LSE

101   values of soil and vegetation used for the actual observation and the sensitivity analysis for

102   the estimated LSE.

103

104   **2. Description of Method**

105   *2.1 NDVI thresholds method*

106   The NDVI thresholds method has been applied to various sensors (Sobrino and

107   Raissouni, 2000; Sobrino et al., 2008; Valor and Caselles, 1996; Peres and DaCamara,

108   2005). The method uses the vegetation coverage information in order to estimate the LSE.

109   The LSE is estimated by;

$$LSE = \varepsilon_{v\lambda}FVC + \varepsilon_{g\lambda}(1 - FVC) + d\varepsilon_\lambda \qquad (1)$$

110   where ε_v and ε_g are vegetation and ground emissivities, respectively. The subscript λ

111   denotes a center wavelength. The method assumes that a surface state of a pixel is

112   composed of a soil and a vegetation. FVC is the fractional vegetation cover and $d\varepsilon$ is a

113   term representing the cavity effect due to the vegetation canopy (i.e. $d\varepsilon = 0$ for flat

114   surfaces). The non-vegetation area (i.e. FVC = 0) is considered as the flat surface. The

115   FVC is simply obtained from the NDVI and two different NDVI threshold values as (Sobrino

116   and Raissouni, 2000; Sobrino et al., 2008);

$$FVC = \left(\frac{NDVI - NDVI_g}{NDVI_v - NDVI_g} \right)^2 \tag{2}$$

117   where $NDVI_g$ and $NDVI_v$ are the bare ground and vegetation NDVIs, respectively. Values of

118    $NDVI_g$ = 0.2 and $NDVI_v$ = 0.5 by Sobrino et al. (2008) to apply the method in global

119   conditions are used in this study since they have been applied to various sensors, such as

120   Advanced Very High Resolution Radiometer (AVHRR) onboard the National Oceanic

121   Atmospheric Administration, Spinning Enhanced Visible and IR Imager (SEVIRI) onboard

122   the Meteosat Second Generation, Moderate Resolution Imaging Spectrometer (MODIS)

123   onboard the Terra and Aqua, Advanced Along Track Scanning Radiometer (AATSR)

124   onboard the Environmental Satellite and Thematic Mapper (TM) onboard the LANDSAT-5.

125   In order to estimate FVC in more detail, however, we should recalculate the $NDVI_g$ and

126    $NDVI_v$ values corresponding to observation sites. Of course, FVC is set to zero when NDVI

127   is less than $NDVI_g$ and unity when it is greater than $NDVI_v$. The NDVI is defined as;

7

$$NDVI = \frac{R_{0.8} - R_{0.6}}{R_{0.8} + R_{0.6}} \tag{3}$$

128 where $R_{0.8}$ is the reflectance observed in the near-infrared band and $R_{0.6}$ is the

129 reflectance observed in the visible (red) band. In the Himawari observation area, previous

130 studies used the polar-orbiting satellite data because GMS and MTSAT series did not have

131 the near-infrared band. The AHI/Himawari-8, however, has near-infrared band as the band

132 4. Hence, we used the band 3 and band 4 to estimate the NDVI. The NDVI data is the

133 maximum NDVI in past 14-day composites. Since NDVI depends on solar zenith angle,

134 band 3 and band 4 data within one hour before-and-after the time of culmination at each

135 pixel are used. An atmospheric correction is not applied since the NDVI thresholds method

136 does not basically require an accurate atmospheric correction for estimation of FVC and

137 NDVI (Sobrino et al., 2008; Li et al., 2013b).

138   The cavity effect term $d\varepsilon$ in Eq. (1) is estimated as;

$$d\varepsilon = \left(1 - \varepsilon_g\right)\varepsilon_v F'(1 - FVC) + \left[(1 - \varepsilon_v)\varepsilon_g G' + (1 - \varepsilon_v)\varepsilon_v F''\right]P_s . \tag{4}$$

139 using a simplified geometrical model assuming the infinitely long Lambertian boxes

140 (Caselles and Sobrino, 1989). Here, the P_s is the side proportion observed by the sensor,

141 and F', G' and F'' are geometrical factors that the fraction of radiation emitted by a side

142 that reaches the ground, the proportion emitted by the ground that reaches a side and the

143 fraction emitted by a side that reaches the adjacent one, respectively (see Fig. 2). These

144 geometrical factors are also given by (Caselles and Sobrino, 1989) as

$$F' = (1 + H/S) - \sqrt{1 + (H/S)^2} \ , \tag{5}$$

$$G' = \tfrac{1}{2}\left[(1 + S/H) - \sqrt{1 + (S/H)^2}\right] \ \text{and} \tag{6}$$

$$F'' = \sqrt{1 + (S/H)^2} - S/H \ . \tag{7}$$

145   Here, H is the height of the hypothetical vegetation elements and S is the distance between

146   them (see Fig. 2). H and S are determined according to a vegetation type. This model does

147   not take into account the shadow influence and double-scattering process. Sobrino et al.

148   (1990) proposed the derivation of P_s considering the case of an observation at a low

149   altitude. In this case, the representation of P_s is quite complicated because P_s of each

150   element in an instantaneous field of view differs greatly depending on satellite zenith angle

151   (SZA) of each element. However, in the case of an observation at a high altitude such as

152   the geostationary satellite, SZAs of each element in an instantaneous field of view are

153   almost same. Hence, we consider the fractional amount by a simplified form without

154   considering the difference of each SZA. Firstly, the simple geometry shows the proportion

155   of the top of cavity element P_t observed by a satellite sensor is constant in SZA θ,

156   whereas the ground proportion P_g linearly decreases as θ increase until the ground

157   disappear from view of the sensor Here, the summation of P_t, P_g and P_s is equal to 1. On

158   the contrary, P_s also increases linearly with θ until the grounds disappear from view of the

159   sensor (until $P_g = 0$), but then after, P_s is constant with increasing θ. Himawari-8 is flying

9

160   at an altitude of 35786 km and the spatial resolutions of the visible and near-infrared bands

161   are 0.5–1.0 km. Thus, the SZAs that the grounds disappear from view of the AHI in one

162   pixel, θ_d, are almost the same. Accordingly, θ_d, P_t and P_s can be expressed as;

$$\theta_d = arctan\left(\frac{S}{H}\right), \tag{8}$$

$$P_t = \frac{F}{F + S}, \tag{9}$$

$$P_s = \begin{cases} \dfrac{(1 - P_t)\theta}{arctan(S/H)}, & \theta < \theta_d \\ 1 - P_t, & \theta \geq \theta_d. \end{cases} \tag{10}$$

163   where F is the width of a box according to a vegetation type. θ is the satellite zenith angle

164   of the AHI.

165   Peres and DaCamara (2005) assumed that the land surfaces in the urban area are flat

166   and are composed the mixture surfaces of construction concrete and paving asphalts.

167   However, the actual surfaces are rough due to the buildings (urban canopy). Therefore, we

168   consider the cavity effects of urban structures as well as the vegetation. The surface

169   emissivity in urban canopy ε_u is estimated as;

$$\varepsilon_u = \varepsilon_t P_t + \varepsilon_s P_s + \varepsilon_g P_g + d\varepsilon_u, \tag{11}$$

$$d\varepsilon_u = (1 - \varepsilon_g)\varepsilon_s F' P_g + \left[(1 - \varepsilon_s)\varepsilon_g G' + (1 - \varepsilon_s)\varepsilon_s F''\right]P_s. \tag{12}$$

170   where ε_t and ε_s are top and side emissivities, respectively. That is, we consider a mixture

171   of the roof (ε_t), wall (ε_s) and ground (ε_g). In case an urban pixel includes vegetation, ε_u

172 substitutes for ε_g in the second term on right side of Eq. (1).

173 The model assumes that vegetation and urban structures are distributed following

174 infinitely long Lambertian boxes. However, the realistic approximation is the distribution of

175 elements as square finite boxes. Caselles et al. (1997) reported the systematic error due to

176 the use of two different geometric models is of the order of 0.1%.

177

178 *2.2 Assignment to the land cover class*

179 As mentioned above, the NDVI thresholds method basically requires the five

180 predetermined value and two input data. The predetermined value are the vegetation and

181 ground emissivities ($\varepsilon_{v\lambda}$ and $\varepsilon_{g\lambda}$) of each AHI TIR band and the scales of Lambertian

182 boxes (F, H, and S) according to a vegetation type. The input data is the NDVI and SZA. In

183 order to set the predetermined values according to vegetation type, these values are

184 defined at each pixel based on the land cover class in accordance with Peres and

185 DaCamara (2005). The land cover classification information is taken from the Global Land

186 Cover by National Mapping Organizations (Tateishi et al., 2011; Tateishi et al., 2014;

187 Kobayashi et al., 2017) version3 (GLCNMO 2013). The GLCNMO2013 is based on MODIS

188 data observed in 2013. It employs 20 different land cover classes and the horizontal

189 resolution is about 500 m. Unlike the International Geosphere-Biosphere Program (IGBP)

190 class, it has the paddy field (class 12), mangrove (class 14) and two types of bare areas

191 (classes 16 and 17) additionally. The GLCNMO2013 data was resampled to the resolution

192 of AHI/Himawari-8. The terrestrial surface is nearly 20% of all Himawari-8 main observation

193 area (85 E–155 W, 60 S–60 N), and the percentage of each land cover class is shown in

194 Table 1. Since the rice farming is flourishing in this area, the paddy fields (class 12)

195 accounts for 3.95% of all land cover. When a paddy field pixel is judged as non-vegetated

196 by NDVI criteria, there are two possibilities, one is the dry soil in fallow period and the other

197 the flooding water surface in rice transplanting period. Thus, the paddy field (class 12)

198 should be considered separately from cropland (class 11 or 13). In this sense,

199 GLCNMO2013 is suitable for the LSE estimation in Asian area.

200   The NDVI threshold method is applied to the classes 1–14 and 16–18. The classes 15

201 (Wetlands) and 19 (Snow/Ice) are given constant emissivity values regardless to seasonal

202 changes of vegetation. In terms of the vegetation emissivity, we used the TIR volumetric

203 bidirectional reflectance distribution function (BRDF) model (Snyder and Wan, 1998) to

204 calculate the BRDF and integrate it over the hemisphere to obtain the directional

205 hemispherical reflectance (DHR) and emissivity from reflectance of each leaf, bark or grass

206 sample measured by laboratories. The TIR volumetric BRDF model form is:

$$f_{vol} = c_1 k_{vol}^\rho + c_2 k_{vol}^\tau + c_3 \tag{13}$$

207 the kernels are given by

12

$$k_{vol}^{\rho} = \frac{(\pi - \xi)cos\xi + sin\xi}{cos\theta_i + cos\theta_r} - \frac{\pi}{2}, \quad (14)$$

$$k_{vol}^{\tau} = \frac{-\xi cos\xi + sin\xi}{cos\theta_i + cos\theta_r}, \quad (15)$$

208   and the coefficients by

$$c_1 = \frac{2\rho}{3\pi^2}[1 - \exp(-bF)], \quad (16)$$

$$c_2 = \frac{2\tau}{3\pi^2}[1 - \exp(-bF)], \quad (17)$$

$$c_3 = \frac{\rho}{3\pi}[1 - \exp(-bF)] + \frac{\rho_0}{\pi}[\exp(-bF)]. \quad (18)$$

209   here θ_i and θ_r are the incident zenith angle and reflected zenith angle; ρ is the leaf, bark

210   or grass reflectance and ρ_0 is the ground reflectance; τ is the leaf transmission; bF is

211   the optical depth; ξ is the scattering angle between incidence and reflection. ξ is given by:

$$\xi = \arccos(cos\theta_i cos\theta_r + sin\theta_i sin\theta_r cos\phi) \quad (19)$$

212   where, ϕ is the relative azimuth angle between the incident and reflected directions. τ is

213   taken to be zero for the TIR region and bF is taken to be infinite (Snyder and Wan, 1998).

214   Therefore, this model requires not a ground reflectance ρ_0 but a leaf, bark or grass

215   reflectance ρ to determine the volumetric BRDFs f_{vol}. The leaf, bark and grass

216   emissivities for each TIR band are weighted by the spectral response function of each TIR

217   band. Table 2 shows the leaf, bark and grass samples assigned to land cover types. These

218   samples   were   selected   from   the   MODIS   UCSB   emissivity   library

13

219 (http://www.icess.ucsb.edu/modis/EMIS/html/em.html; Wan et al., 1994) and the ASTER

220 spectral library (http://speclib.jpl.nasa.gov/; Baldridge et al., 2009) and were based on the

221 available spectra as representing the general features of trees though more kinds of

222 vegetation should be considered. The seasonal change of vegetation is considered as

223 green and senescent states (Snyder et al., 1998). The seasonal states, green or senescent

224 of each pixel are judged by using the maximum NDVI in past 14-day composites and the

225 annual mean NDVI value consist of 12 periods of 30-day composite as the thresholds. If the

226 maximum NDVI in past 14-day composites of a pixel is greater (smaller) than the annual

227 mean NDVI of the same pixel, the seasonal state of the pixel is judged as green

228 (senescent). The combination ratios of classes 5–10, class 13 and classes 15–18 were

229 determined by referring to Peres and DaCamara (2005). The vegetation emissivity ($\varepsilon_{v\lambda}$)

230 used for the predetermined value is considered as the mean value of the vegetation

231 emissivities of the materials for each class.

232 The paddy field (class 12) has three characteristics periods, such as the flooding and rice

233 transplanting period, the growing period and the fallow period (Xiao et al., 2002). The state

234 for the paddy field is sub-divided as shown in Table 2. The growing period in the green

235 state may means vegetative growth stage or reproductive stage, while the growing or the

236 fallow period in the senescent state may mean ripening stage or weeds in the fallow period.

237 In order to judge the flooding and rice transplanting period, the difference between

238 normalized difference water index (NDWI) and NDVI values (Xiao et al., 2002) consist of

239 14-day composites is used. The NDWI is defined as;

$$NDWI = \frac{R_{0.8} - R_{1.6}}{R_{0.8} + R_{1.6}} \tag{20}$$

240 where $R_{0.8}$ and $R_{1.6}$ are the reflectance of near-infrared observed in band 4 and band 5

241 of AHI, respectively. If a pixel of paddy field has smaller NDVI than NDWI, the pixel is

242 judged as water body and is considered as the wetland (class 15).

243 The ground emissivity is also evaluated based on the MODIS UCSB emissivity library

244 and the ASTER spectral library. Each land class is assumed to be covered by materials

245 listed in Table 3. The gross emissivity of each material, for example 'Inceptisol', is

246 computed by integrating the spectral emissivity in library with the weight of sensor response

247 function over the band width. When sub-materials exist, the value is averaged over the

248 sub-materials. It is worth noting that classes 15 (Wetlands) and 19 (Snow/Ice) are also

249 listed in Table 3 though the NDVI threshold method is not applied. The ground emissivity of

250 each class ($\varepsilon_{g\lambda}$) is computed as the mean over component materials in Table 3. The Table

251 3 is modified from the corresponding table in Peres and DaCamara (2005) considering the

252 difference in soil components Asia and Oceania from Europe and Africa region. The soil

253 and rock materials of each land cover are decided by referring to the global soil regions

254 map (https://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/use/?cid=nrcs142p2_054013).

255 The soil type under broadleaf evergreen forest (class 1) in the tropical zone, is actually

256 'ultisols' but is assumed as in Table 3. It is because the 'ultisols' are not included in ASTER

257 library, but it may not cause much problem since the ground surfaces are usually covered

258 by the crown canopy and the forest floor in these tropical forests. The ground material in the

259 mangrove (class 14) is set as water, though it has a property of broadleaf evergreen forest.

260 For the snow/ice surfaces, the areas other than class 19 sometimes be also covered by

261 snow or ice. Considering this case, the snow/ice surfaces are detected using the

262 normalized difference snow and ice index (NDSII) in addition to the region in class 19. The

263 NDSII is defined as (Xiao et al., 2001);

$$NDSII = \frac{R_{0.6} - R_{1.6}}{R_{0.6} + R_{1.6}} \qquad (21)$$

264 The NDSII data is obtained by past 4-day composites. When NDSII of a pixel is greater

265 than 0.4, the mean emissivity of snow and ice is assigned to the pixel. Although the

266 atmospheric correction is required to calculate the NDWI, NDVI and NDSII in more detail, it

267 is not considered and is a future task in this study.

268 Table 4 shows the scales of Lambertian boxes (F, H, and S) of each vegetation type.

269 These values were set based on Sobrino et al. (1990), Valor and Caselles (1996) and

270 Peres and DaCamara (2005). The forest regions are assumed to be short separation and

271 high boxes. Shrub, sparse and unforested regions are assumed to be long separation and

272 low boxes. The length assumed at each face has a reasonable range. We calculate all $d\varepsilon$

273 by combinations of three lengths and then consider the mean $d\varepsilon$ as the representative

16

274 value of each class.

275 Since we are to use the retrieved LST to the research in urban environment study, a

276 special attention is payed for urban canopy effect. The geometrical model for surface

277 emissivity in urban area also requires the surface emissivities of the top, side and ground of

278 each AHI TIR band and the scales of Lambertian boxes (F, H, and S) according to urban

279 canopy. Table 5 shows the manmade materials and the scales applied to each face of

280 urban structure. The scales of urban structure were based on Moriwaki et al. (2002),

281 Strømann-Andersen and Sattrup (2011) and Ito et al. (2015). The roofing (top) materials

282 are considered the rubbers and shingles except for the metals. The wall (side) materials are

283 considered the construction concretes except for bricks, window glasses, paints and woods.

284 The urban structures have various characteristics by a degree of development, such as

285 commercial, industrial and residential area. Although it is possible to set values

286 corresponding to each urban structure by using more detailed land use data (Yang et al.,

287 2015a, b), we made a rough estimate by assuming an average structure. The mean $d\varepsilon_u$ of

288 all combinations of three lengths are calculated as the representative cavity effect due to

289 the urban canopy. Note that the internal reflection due to the trees cannot occur over the

290 roof faces since assumed building height is higher than the assumed tree height in Table 3.

291 Therefore, when we calculate the cavity effect in urban area due to the trees using Eq. (4),

292 the ground emissivities are considered as consisting construction concretes, road asphalts

293 and tar, not ε_u (Eq. 11).

294

3. Results and Discussions

296 *3.1. Vegetation and ground emissivity*

297   Table 6 and 7 show the emissivities of vegetation and ground for each land cover class

298 as derived by the procedure described in the previous section. For the vegetation, both

299 green and senescent states are listed. The deviation (Dev.) is computed by considering the

300 experimental error of each component material consisting a class. The experimental errors

301 of emissivity in the laboratory and the field measurements are assumed as ± 0.005

302 (Caselles et al., 1997). The 'Dev.' is calculated as;

$$\text{Dev.} = \sqrt{\frac{1}{3n-1}\left\{\sum_{i=1}^{n}(\varepsilon_i - \bar{\varepsilon})^2 + \sum_{i=1}^{n}(\varepsilon_i + 0.005 - \bar{\varepsilon})^2 + \sum_{i=1}^{n}(\varepsilon_i - 0.005 - \bar{\varepsilon})^2\right\}} \quad (22)$$

303 where n is a number of component materials of each class and $\bar{\varepsilon}$ is mean emissivity of

304 each class. The vegetation has basically higher emissivity and lower deviation than soils or

305 rocks. The senescent vegetation has lower emissivity and higher deviation than the green

306 vegetation. The class 16 (bare area, consolidated) has the lowest emissivity and the

307 highest deviation in the ground emissivity. Table 8 shows the emissivity and deviation at

308 each face of urban structure corresponding to Table 5. The deviations are also calculated

309 considering ± 0.005 experimental error of component materials. The deviation is high

18

310 especially at the top. This is because the roofing materials have a large variety in emissivity.

311 The values for band 13, 14, 15 range, respectively, from 0.8598 to 0.9661, 0.9177 to

312 0.9725 and 0.9288 to 0.9808. If the metal roofing materials and window glasses are

313 considered, there is a possibility of higher deviation because these emissivities are quite

314 low less than 0.8.

315

316 *3.2. Magnitude of the cavity effect*

317 The cavity effect of vegetation, $d\varepsilon$, is shown in Fig. 3 as functions of SZA and FVC for

318 the green state. The left-hand column of Fig. 3 shows the SZA dependences of $d\varepsilon$ for

319 three TIR bands. They were calculated assuming the FVC = 0.5. The right-hand column

320 shows the FVC dependences for three TIR bands. They were calculated assuming the SZA

321 = 20 °. $d\varepsilon$ values are greatly varied with vegetation type, and $d\varepsilon$ of classes 1, 2, 3, 4 and

322 5 are especially high. Conversely, $d\varepsilon$ of the regions assumed low-height trees and

323 long-separation between them, such as classes 10, 16, 17, 18 are less than 0.01. Thus, we

324 may not consider the cavity effects in those regions. The $d\varepsilon$ slightly increases with

325 increasing SZA, while it obviously decreases with increasing FVC. In reality, the FVC (the

326 side proportion) is not constant but increases with increasing SZA. Therefore, as mentioned

327 by Valor and Caselles (1996), it is considered that $d\varepsilon$ decreases with increasing SZA.

328 The cavity effect due to the urban structure, $d\varepsilon_u$, for SZA ranging from 0° to 60° is shown

329   in Table 9. The $d\varepsilon_u$ of band 13 and 14 are greater than 0.01 for all the SZAs and $d\varepsilon_u$ of

330   band 15 is approximately 0.01. Atitar and Sobrino, (2009) reported that the emissivity error

331   greater than 0.01 causes the LST retrieval error of approximately 1 K. Hence, it is

332   necessary to consider the cavity effect in the urban areas same as the vegetation. Yang et

333   al. (2015a) estimated the LSE in TIR band of the Landsat 8 in urban area using the building

334   GIS data. They reported the differences reach 0.02 between the material emissivity and

335   effective emissivity considered the cavity effect especially over built-up areas. Table 10

336   shows the urban surface emissivity ε_u and $d\varepsilon_u$ of two geometrical shapes; one has a

337   large $d\varepsilon_u$ (type A: F = 10 m, H = 15 m, S = 20 m) and the other has a small $d\varepsilon_u$ (type B: F

338   = 20 m, H = 7 m, S = 10 m) for three TIR bands in the SZA ranging from 0° to 60° at

339   intervals of 20°. The ε_u and $d\varepsilon_u$ differences between type A and B are shown at the

340   bottom of the Table 10. Both types of A and B are assumed for estimation of $d\varepsilon_u$ in this

341   study as shown in Table 5. $d\varepsilon_u$ of type A for band 13 certainly reaches 0.02. The ε_u and

342    $d\varepsilon_u$ differences between type A and B for band 13, 14 are greater than 0.01. Therefore, if

343   we observe the urban areas in more detail, it should require the land use data having a

344   higher spatial resolution, such as the building GIS data. The similar sophisticated method

345   may be possible for other vegetation and/or bare soil areas, if the detailed *in situ* database

346   is available. Then, it will be possible to acquire the more detail ε_v, ε_u (ε_g), F, H, S

347   information.

348

3.3. Seasonal and dynamic changes of LSE

Figure 4 shows the time changes of LSEs for three AHI TIR bands, NDVI and NDSII over

a cropland in Japan (42.74°N, 143.14°E) from August 2015 to December 2015. The NVDI

decreases gradually through the observed term. On the other hand, the LSEs suddenly

decrease in late October when NDVI becomes smaller than a threshold for the judgment of

seasonal state of the pixel. After the decrease, the LSEs are constant or a little increasing.

In this period, the cavity effect of vegetation increases with decreasing FVC in November.

In December, the sudden changes of the NDSII and LSEs due to snow/ice coverage are

observed.

When a land surface is covered by snow/ice, the observed value of NDVII becomes low.

Thus, a LSE estimation error due to the misjudgment of snow/ice coverage is almost same

as the difference between ground emissivity of each class and snow/ice emissivity of class

19 (see Table 7).

Figure 5 shows the time changes of LSEs for three AHI TIR bands, NDVI and NDWI over

a paddy field in Japan (37.58°N, 138.85°E) from April 2016 to June 2016. The NDVI is

generally larger than the NDWI. However, the NDWI becomes larger than the NDVI from

May to early June. This is due to the flooding and rice transplanting. The LSEs change

according to this inversion of the relation between NDVI and NDWI. If the NDWI is not

367 considered, the LSE for the flooding and rice transplanting period is assigned as near the

368 value of ground emissivity. Thus, the LSE estimation error due to the misjudgment of

369 flooding is near the difference between the ground emissivity of class 12 and the emissivity

370 of class 15 (see Table 7). The misjudgments of seasonal and dynamic states, such as

371 senescent vegetation, snow/ice coverage and flooding in the paddy field may cause large

372 LSE error. Although these are the inherent disadvantages of the classification based

373 method and the NDVI thresholds method, our considerations using NDSII and NDWI

374 reduce the errors.

375

376 *3.4. Sensitivity analysis*

377 The *in-situ* evaluation of LSE is practically impossible, so that we assess the possible

378 total LSE error for each class instead. We perform a sensitivity analysis as regard to input

379 data. Based on Eq. (1) – (10), the total LSE error is defined as (Caselles et al., 1997)

$$\delta\varepsilon_\lambda = \left|\frac{\partial\varepsilon_\lambda}{\partial\varepsilon_{\lambda v}}\right|\delta\varepsilon_{\lambda v} + \left|\frac{\partial\varepsilon_\lambda}{\partial\varepsilon_{\lambda g}}\right|\delta\varepsilon_{\lambda g} + \left|\frac{\partial\varepsilon_\lambda}{\partial P_v}\right|\delta FVC + \left|\frac{\partial\varepsilon_\lambda}{\partial F}\right|\delta F + \left|\frac{\partial\varepsilon_\lambda}{\partial H}\right|\delta H + \left|\frac{\partial\varepsilon_\lambda}{\partial S}\right|\delta S \quad (23)$$

380 The emissivity errors of each class ($\delta\varepsilon_{\lambda v}$ and $\delta\varepsilon_{\lambda g}$) are computed by considering ± 0.005

381 experimental errors for all materials and bands (i.e., these errors are equal to Dev. of each

382 class as shown in Table 6 and 7). F, H and S errors are assumed as 10% of their value (i.e.,

383 δF, δS and δH are the deviations corresponding to the errors of $\pm 0.1F$, $\pm 0.1S$ and

384 $\pm 0.1H$). For example, when we calculate δF for F = 1.0 m of the class 1, δF is calculated

22

385   as $\sqrt{\frac{1}{2}\{(1.1-1.0)^2+(0.9-1.0)^2\}}$. These emissivity and shape errors are based on

386   Caselles et al. (1997). For the proportions of F, H and S, Caselles et al. (1997) considered

387   a mixed pixel of FVC = 0.5 and an SZA of P_s = 0.2 and P_t = 0.3. Instead, we consider a

388   situation; FVC = 0.5 and SZA = 20°. On this basis, the FVC estimation error is assumed to

389   vary between 5 % and 25 %, which is an appropriate estimation error range based on

390   vegetation indices (Caselles et al., 1997; Peres and DaCamara, 2005). Urban canopy is

391   additionally considered in this study. Therefore, instead of $\delta\varepsilon_{\lambda g}$, for urban area, $\varepsilon_{\lambda gu}$, is

392   calculated by

$$\delta\varepsilon_{\lambda gu} = \left|\frac{\partial\varepsilon_\lambda}{\partial\varepsilon_{\lambda t}}\right|\delta\varepsilon_{\lambda t} + \left|\frac{\partial\varepsilon_\lambda}{\partial\varepsilon_{\lambda s}}\right|\delta\varepsilon_{\lambda s} + \left|\frac{\partial\varepsilon_\lambda}{\partial\varepsilon_{\lambda g}}\right|\delta\varepsilon_{\lambda g} + \left|\frac{\partial\varepsilon_\lambda}{\partial F}\right|\delta F + \left|\frac{\partial\varepsilon_\lambda}{\partial H}\right|\delta H + \left|\frac{\partial\varepsilon_\lambda}{\partial S}\right|\delta S \quad (24)$$

393   The top, side and ground emissivity errors, $\delta\varepsilon_{\lambda t}$, $\delta\varepsilon_{\lambda s}$ and $\delta\varepsilon_{\lambda g}$, are computed by

394   considering ± 0.005 experimental errors for all materials and bands (i.e., these errors are

395   equal to Dev. of each class as shown in Table 8). F, H and S errors for urban canopy are

396   also assumed as 10% of their value.

397   Figure 6 shows the total LSE error of each GLCNMO class and TIR band for two

398   seasonal states. The left-hand column of Fig. 6 is for the green state and the right-hand

399   column is for the senescent state. The total LSE error for senescent state is excluded the

400   evergreen-vegetation classes (classes 1, 3 and 14), class 15 (wetland) and class 19

401   (snow/ice). Since the NDVI thresholds method is not applied to the classes 15 and 19, they

402   are not affected by the FVC estimation error. The LSE error for band 13 is the highest of the

403   three TIR bands. While the errors of most classes for band 14 and 15 are less than 0.01,

404   the errors of classes 16 and 18 for band 13 are greater than 0.01 and especially the error of

405   class 18 reaches approximately 0.015. It is thought that the error of class 16 is caused by

406   the large deviation of ground emissivity (see Table 7) and the error of class 18 is caused by

407   not only the large deviation of ground and top emissivity (see Table 8) but also the large

408   instability of $d\varepsilon_u$ due to urban surface structure (see Table 10). On the other hand, the

409   areas classified as the forest (classes 1, 2, 3, 4, 5 and 14) have the quite low LSE errors,

410   even the LSE errors for band 13 are less than 0.005. Furthermore, the influences of the

411   FVC estimation error for these classes are very small.

412   The above results except for urban (class 18) have the estimation accuracy comparable

413   to previous studies with the semi-empirical method (Snyder et al., 1998; Peres and

414   DaCamara, 2005). For the urban area, it is obvious that the large LSE error occurred in the

415   spatial resolution of global map (approximately 0.01°) by making a rough estimate of urban

416   surface structure.

417

418   *3.5. Possible misclassification in GLCNMO2013*

419   The LSE error due to misclassification of land cover map should also be considered.

420   Kobayashi et al. (2017) reported the misclassification ratio of GLCNMO2013, in that

421   classification accuracies in some forest types (classes 2-11 and 13) are low. The "user's

422   accuracies" of these classes range from 47% to 79% and "the producer's accuracies" range

423   from 48% to 74%. Evergreen forest (class 1) and mangrove (class 14) have more than 84%

424   of user's accuracies and more than 90% of producer's accuracies. Paddy field (class 12)

425   has 84% of user's accuracy and 77% of producer's accuracy. It is generally difficult to

426   distinguish among different forest types, so that the similar tendency of misclassification is

427   found in other global land cover maps, such as the International Geosphere-Biosphere

428   Program Data and Information System (IGBP-DIS) and the MODIS MOD12Q1 land-cover

429   product (Peres et al., 2005). For other classes, wetland (class 15) has 87% of user's

430   accuracy and 65% of producer's accuracy. Bare area, consolidated (class 16) has 78% of

431   user's accuracy and 76% of producer's accuracy. Bare area, unconsolidated (class 17) has

432   89% of user's and producer's accuracies. Urban (class 18) has 100% of user's accuracy

433   and 98% of producer's accuracy. Snow/ice (class 19) has 98% of user's and producer's

434   accuracies.

435   The misclassification is most likely to occur within different vegetation classes. Both

436   vegetation and ground emissivity differences between vegetation classes for the green

437   state are less than 0.01 for three bands (see Table 6 and 7). For the senescent state,

438   however, the vegetation emissivity difference may reach to about 0.015 (e.g., the difference

439   between classes 7 and 8 in band 14). Another source of the misclassification resides in

440   bare areas (classes 16 and 17), which may cause larger LSE error (about 0.02–0.05). As

25

441   described in the section 2.2, different emissivity assignment methods are applied to the

442   paddy field, urban, wetland and snow/ice. The misclassification in these classes leads to

443   the misapplication between the methods, which may cause large LSE error. Fortunately,

444   paddy field, urban, wetland and snow/ice have high classification accuracies. Therefore, it

445   is thought that the misapplication of emissivity assignment is expected to small.

446

447   *3.6. Influence on LST estimation*

448   Yamamoto et al. (2017) evaluated the sensitivities of their newly developed LST

449   algorithm, nonlinear three-band algorithm, to the uncertainties of LSEs for three bands (±

450   0.02) and compared with other existing algorithms, nonlinear split-window algorithm by

451   Sobrino and Romaguera (2004) and three-band algorithm by Sun and Pinker (2003). The

452   nonlinear three-band algorithm has a LST calculation formula which is improved by adding

453   quadratic terms of the difference between 2 brightness temperatures into the three-band

454   algorithm by Sun and Pinker (2003). The algorithm makes the maximum use of AHI window

455   TIR bands, bands 13, 14 and 15. It is reported that the LST estimation error caused by the

456   ± 0.02 LSE uncertainties for the nonlinear split-window, three-band and nonlinear

457   three-band algorithms are 2.90 K, 3.00 K and 1.84 K (at nadir), respectively. The sensitivity

458   analysis for LSE estimation (Fig. 6) ensures smaller LST estimation error than their derived

459   LST errors. The misjudgments of seasonal and dynamic states may cause ± 0.02 LSE error

460　in maximum, which in turn yield the LST error evaluated by Yamamoto et al. (2017).

461　Therefore, the LSE error influence on the final LST retrieval accuracy is concluded within

462　the allowable range. Only the misclassification in bare areas (classes 16 and 17), however,

463　may cause larger LST error since the ground emissivity difference between them is large.

464

465　**4. Conclusions**

466　　The LSE maps for AHI three TIR bands were developed by using a semi-empirical

467　method based on Peres and DaCamara (2005). These are to be used in the LST retrieval

468　from Hiamwari-8. Peres and DaCamara (2005) assigned the emissivity value of the mixture

469　of vegetation and soil to each pixel based on the IGBP land cover class. The fractional

470　vegetation cover of each pixel is estimated from the NDVI observation. Because the AHI

471　also has visible and near-infrared bands which is needed to calculate the NDVI, it becomes

472　possible to apply their method. In this study, the land cover classification information is

473　taken from the GLCNMO2013 and material emissivities of soil, vegetation and others are

474　taken from the MODIS UCSB emissivity library and the ASTER spectral library.

475　　We newly added three considerations over Peres and DaCamara (2005). In order to

476　consider phenology, two seasonal states, green and senescent, are considered by using

477　the NDVI value on the basis of the annual mean NDVI consist of 12 periods of 30-day

478　composite. Accordingly, slightly lower emissivity is assigned to the senescent state and

479   higher emissivity value is assigned to the green state. Secondly, the flooding and rice

480   transplanting period in the paddy fields and snow/ice coverage are detected using the

481   NDWI, NDVI and NDSII. When a pixel is covered by snow/ice, the emissivity value of

482   snow/ice is assigned independent to the pixel class. For paddy fields, when a pixel is

483   judged as the flooding and rice transplanting period, the high emissivity value that has both

484   grass and water properties is assigned. Thirdly, the cavity effect due to the urban canopy is

485   considered by extending the geometrical model for vegetation canopy proposed by

486   Caselles and Sobrino, (1989). Several typical urban structures and the gross emissivity of

487   each face of urban structure are assumed. Peres and DaCamara (2005) assumed that the

488   land surfaces in the urban area are flat, and reported that the estimation error was low.

489   However, our result shows that the average value of the cavity effect on LSE is as large as

490   0.01 and it varies greatly depending on the urban structure. It reaches to 0.02 especially

491   over built-up area. The total LSE error is also estimated. It was especially high in urban

492   area. Thus, it is obvious that the cavity effect of urban structure cannot be ignored even in

493   global (approximately 1 km) scale.

494   The sensitivity analysis shows that the total LSE errors for three bands are less than 0.02.

495   The error is especially stable at the vegetation area, where it is less than 0.01. However, we

496   have to pay attention to the misclassification in bare areas and the misjudgments of

497   seasonal and dynamic states, which may cause large LSE error. Because this accuracy of

498   the LSE is comparable to that of previous studies (Snyder et al., 1998; Peres and

499   DaCamara, 2005), the LSE maps are sufficiently applicable to the multi-channel LST

500   algorithm, such as a split-window algorithm and a three-band algorithm. Our LSE product

501   may also provide initial-guess estimates for the two-temperature method (TTM) that

502   retrieve the LST and LSE simultaneously (Peres and DaCamara, 2004).

638

639   Fig. 5   The upper graph is the time changes of LSEs for band 13, 14 and 15 over a paddy

640   field in Japan (37.58°N, 138.85°E) from April to June, 2016. The lower graph is the time

641   changes of NDVI and NDWI corresponding to the above graph.

642

643   Fig. 6   The LSE error for each GLCNMO class and TIR band. The left figures show the

644   LSE error in green state and the right figures show the LSE error in senescent state.

645

646
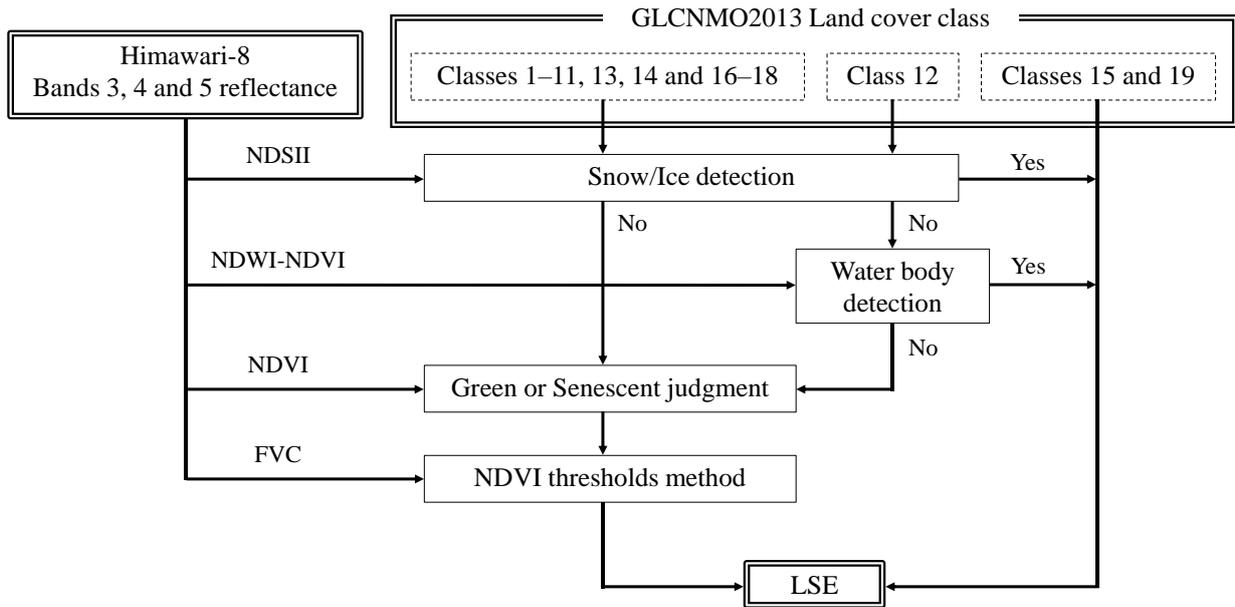

Fig. 1   The flowchart of the procedure for the LSE estimation method. Classes 1–11, 13,

14 and 16–18 are the land cover areas applied the NDVI thresholds method. Class 12 is

the paddy field that have specific seasonal variation, such as the flooding and rice

transplanting period, the growing period and the fallow period. Classes 15 and 19 are

wetland and snow/ice, respectively. The LSE in these two classes are considered as

unchanged value by the seasonal change of vegetation.

653

654
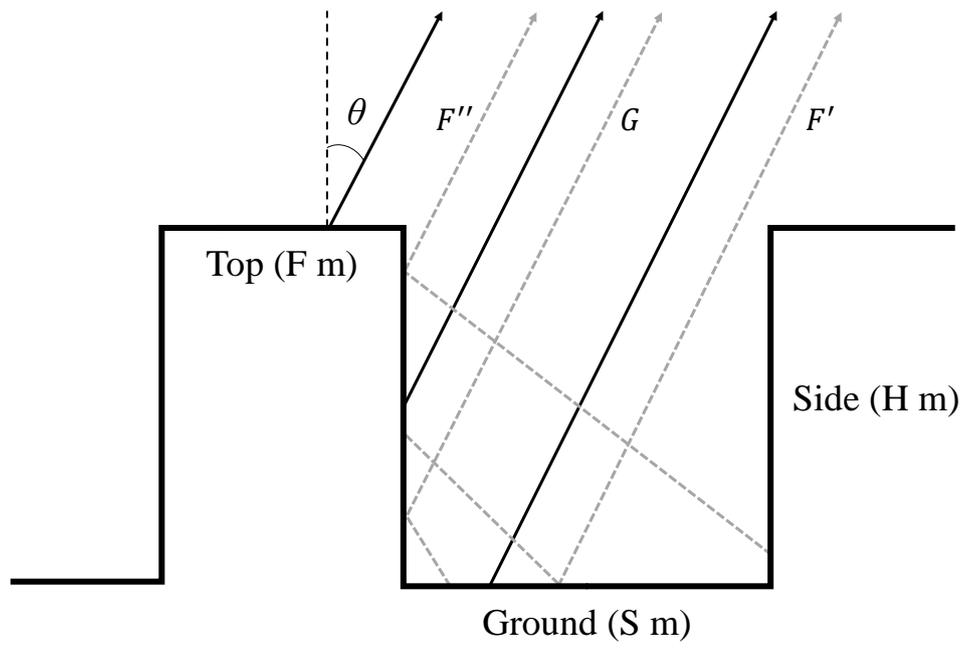

Fig. 2   A schematic view of direct radiances and first reflections in a Lambertian box for

describing a rough surface.

657
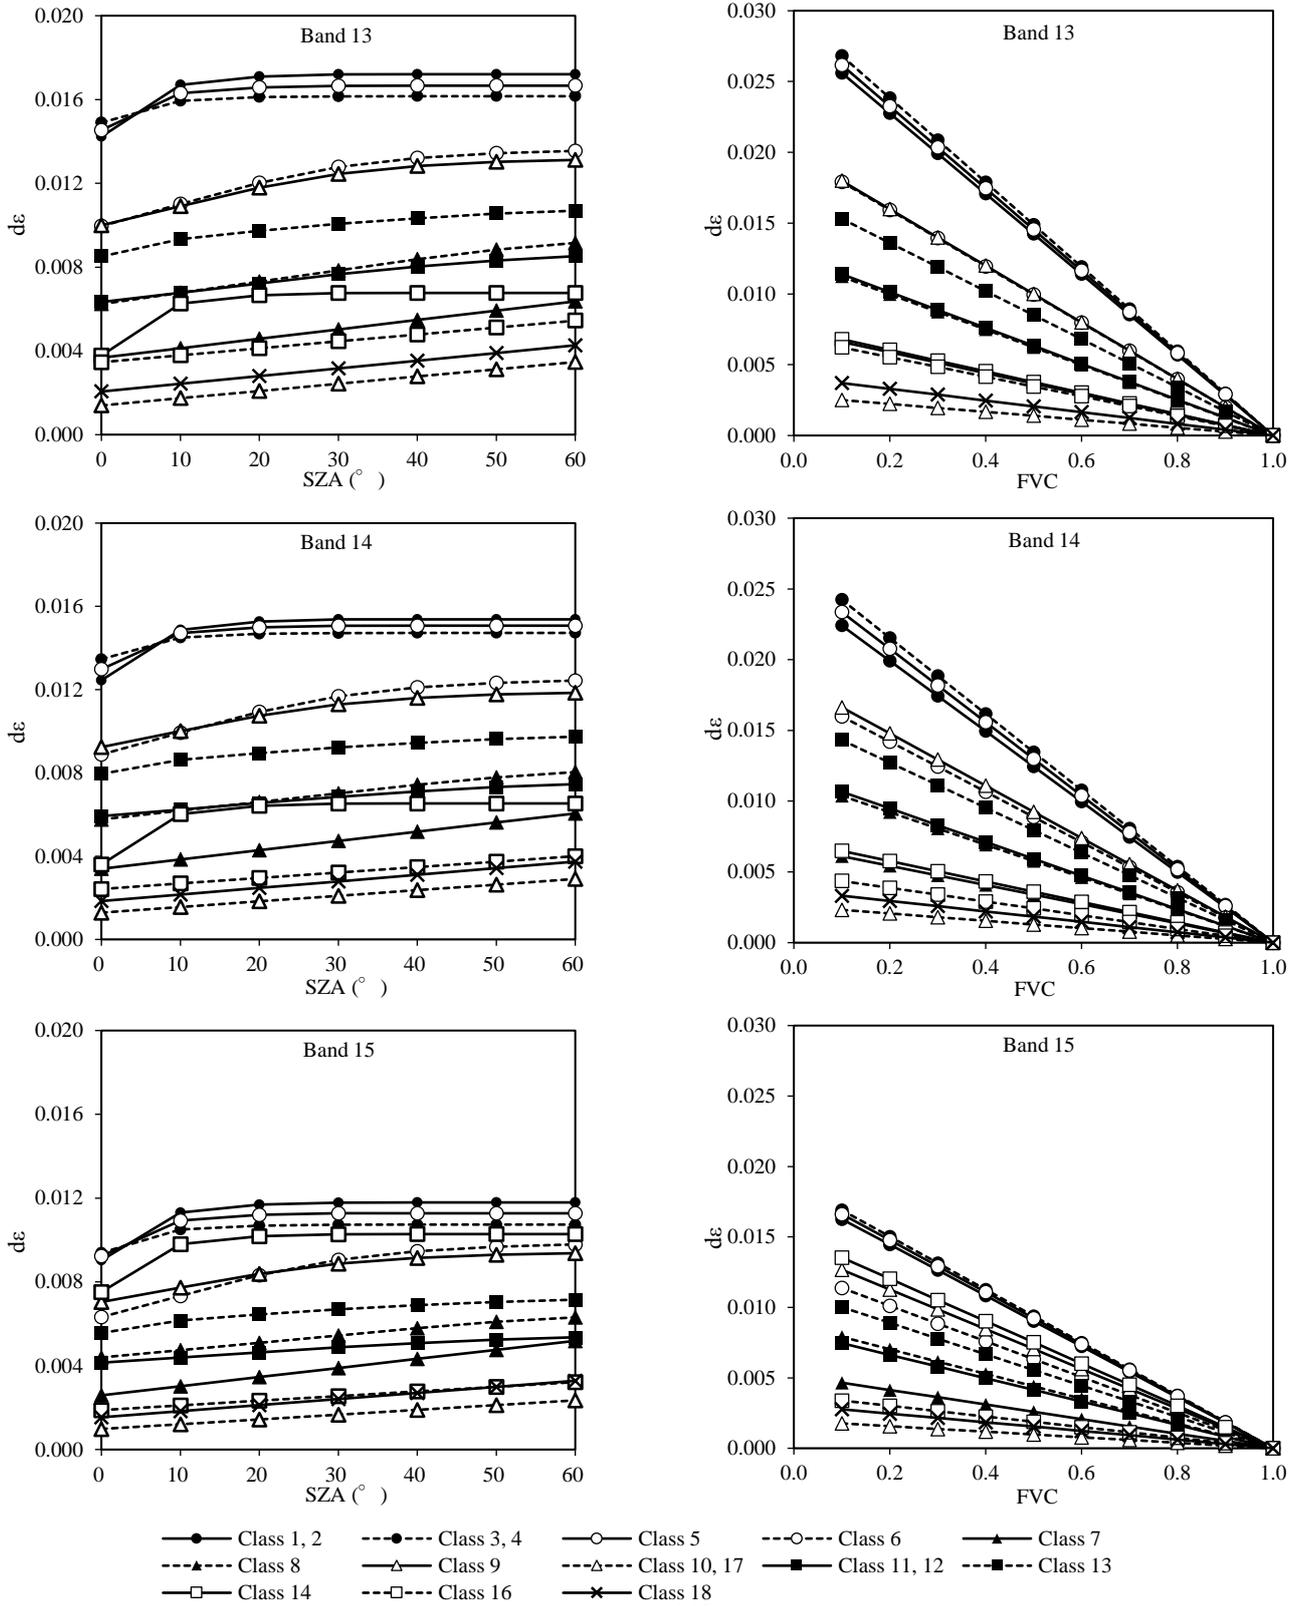

Fig. 3   The SZA and FVC dependence of the cavity effect (dε) for each land cover. The left

figures show the SZA dependence for band 13, 14 and 15. The right figures show the

FVC dependence for band 13, 14 and 15.

40

661
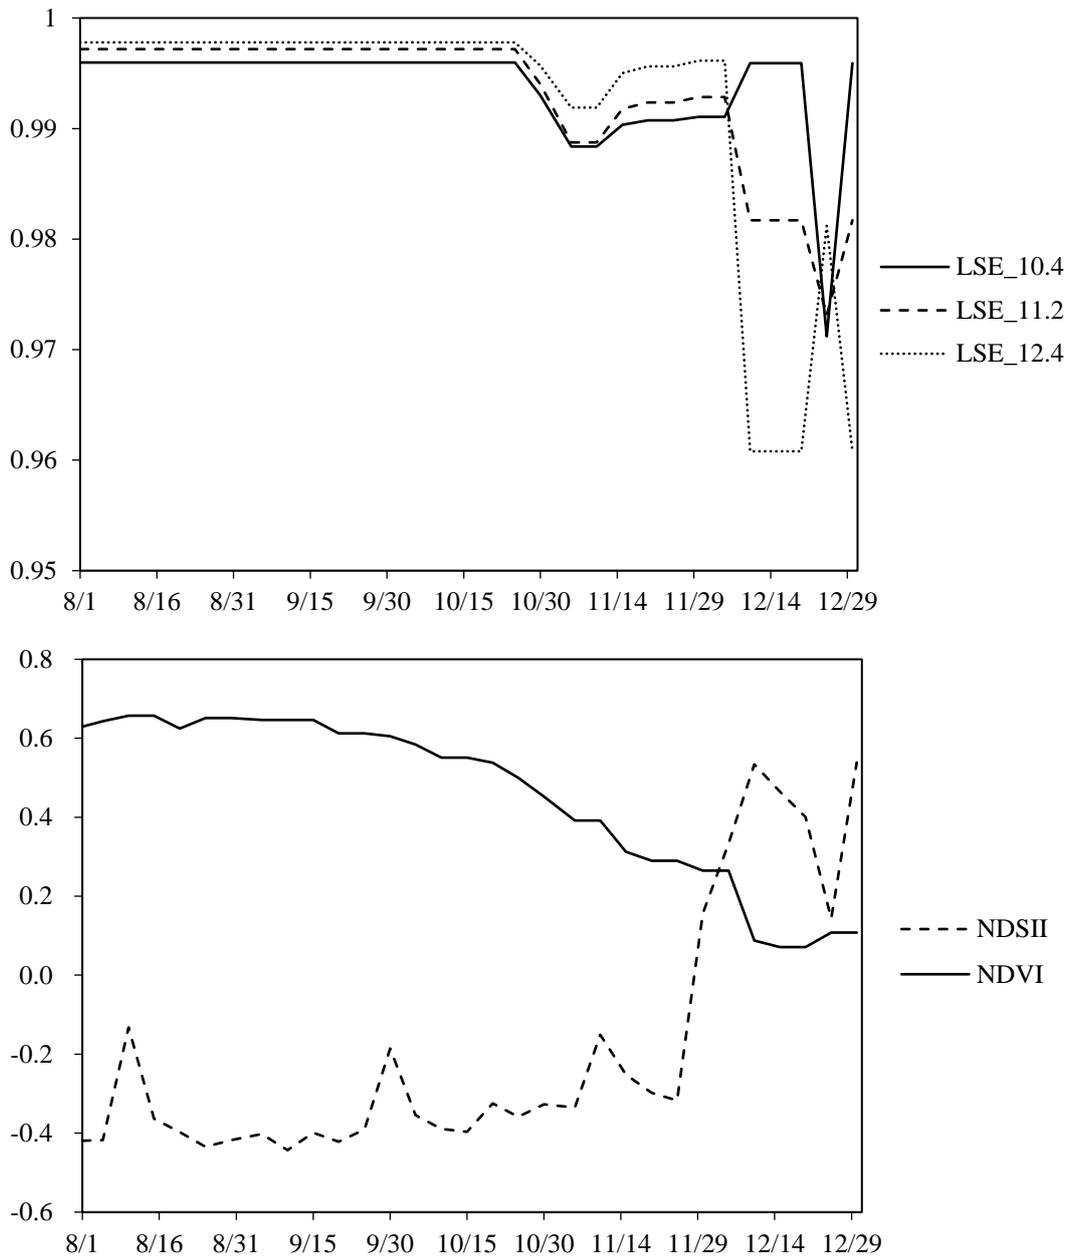

Fig. 4   The upper graph is the time changes of LSEs for band 13, 14 and 15 over a

cropland in Japan (42.74°N, 143.14°E) from August to December, 2015. The lower graph is

the time changes of NDVI and NDSII corresponding to the above graph.

665

666
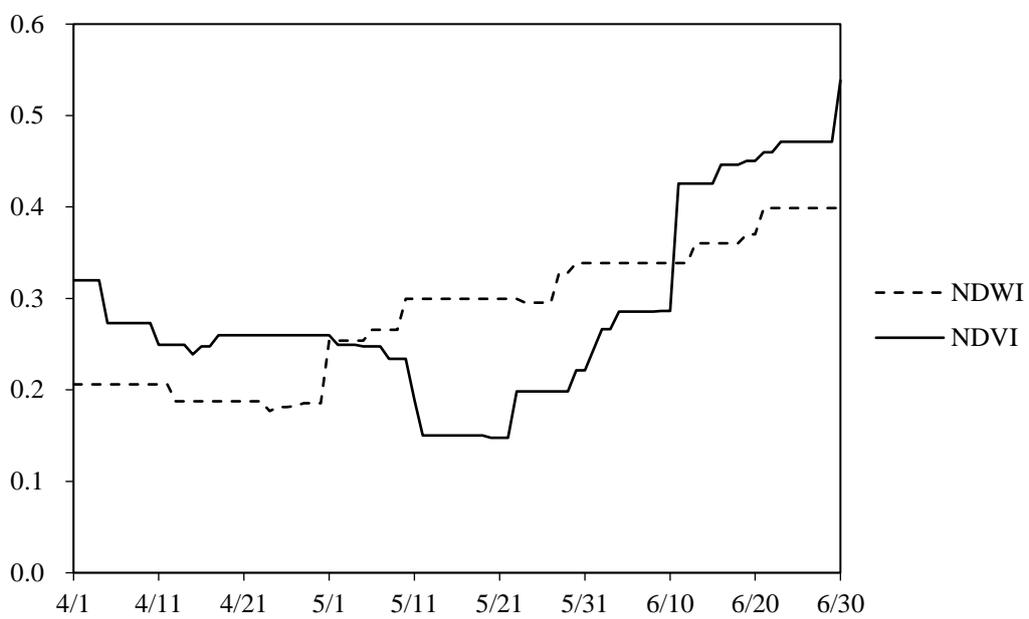

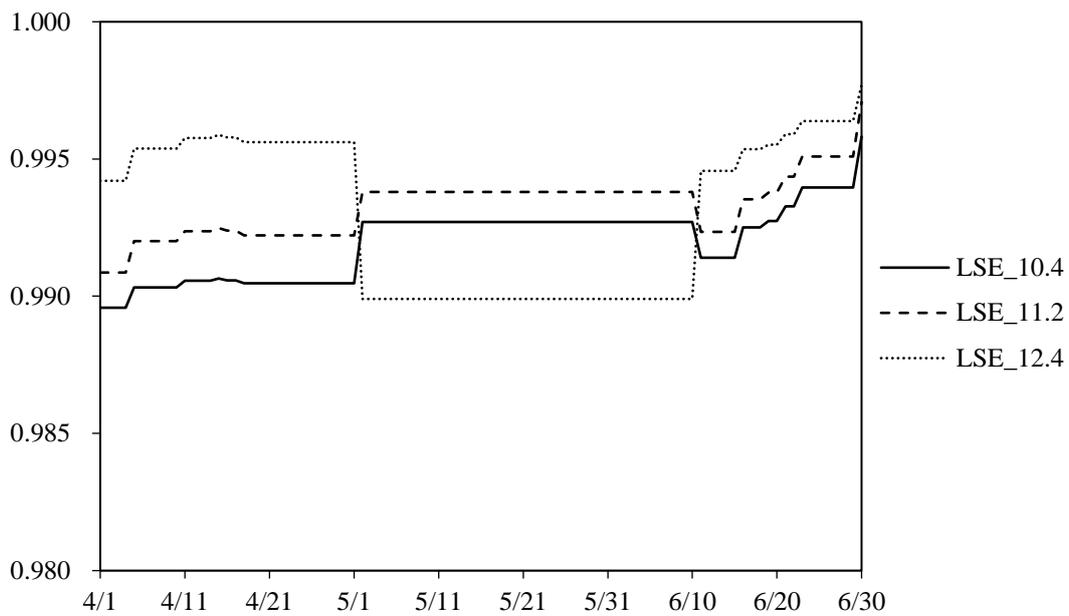

667

668   Fig. 5   The upper graph is the time changes of LSEs for band 13, 14 and 15 over a paddy

669   field in Japan (37.58°N, 138.85°E) from April to June, 2016. The lower graph is the time

670   changes of NDVI and NDWI corresponding to the above graph.

671

672
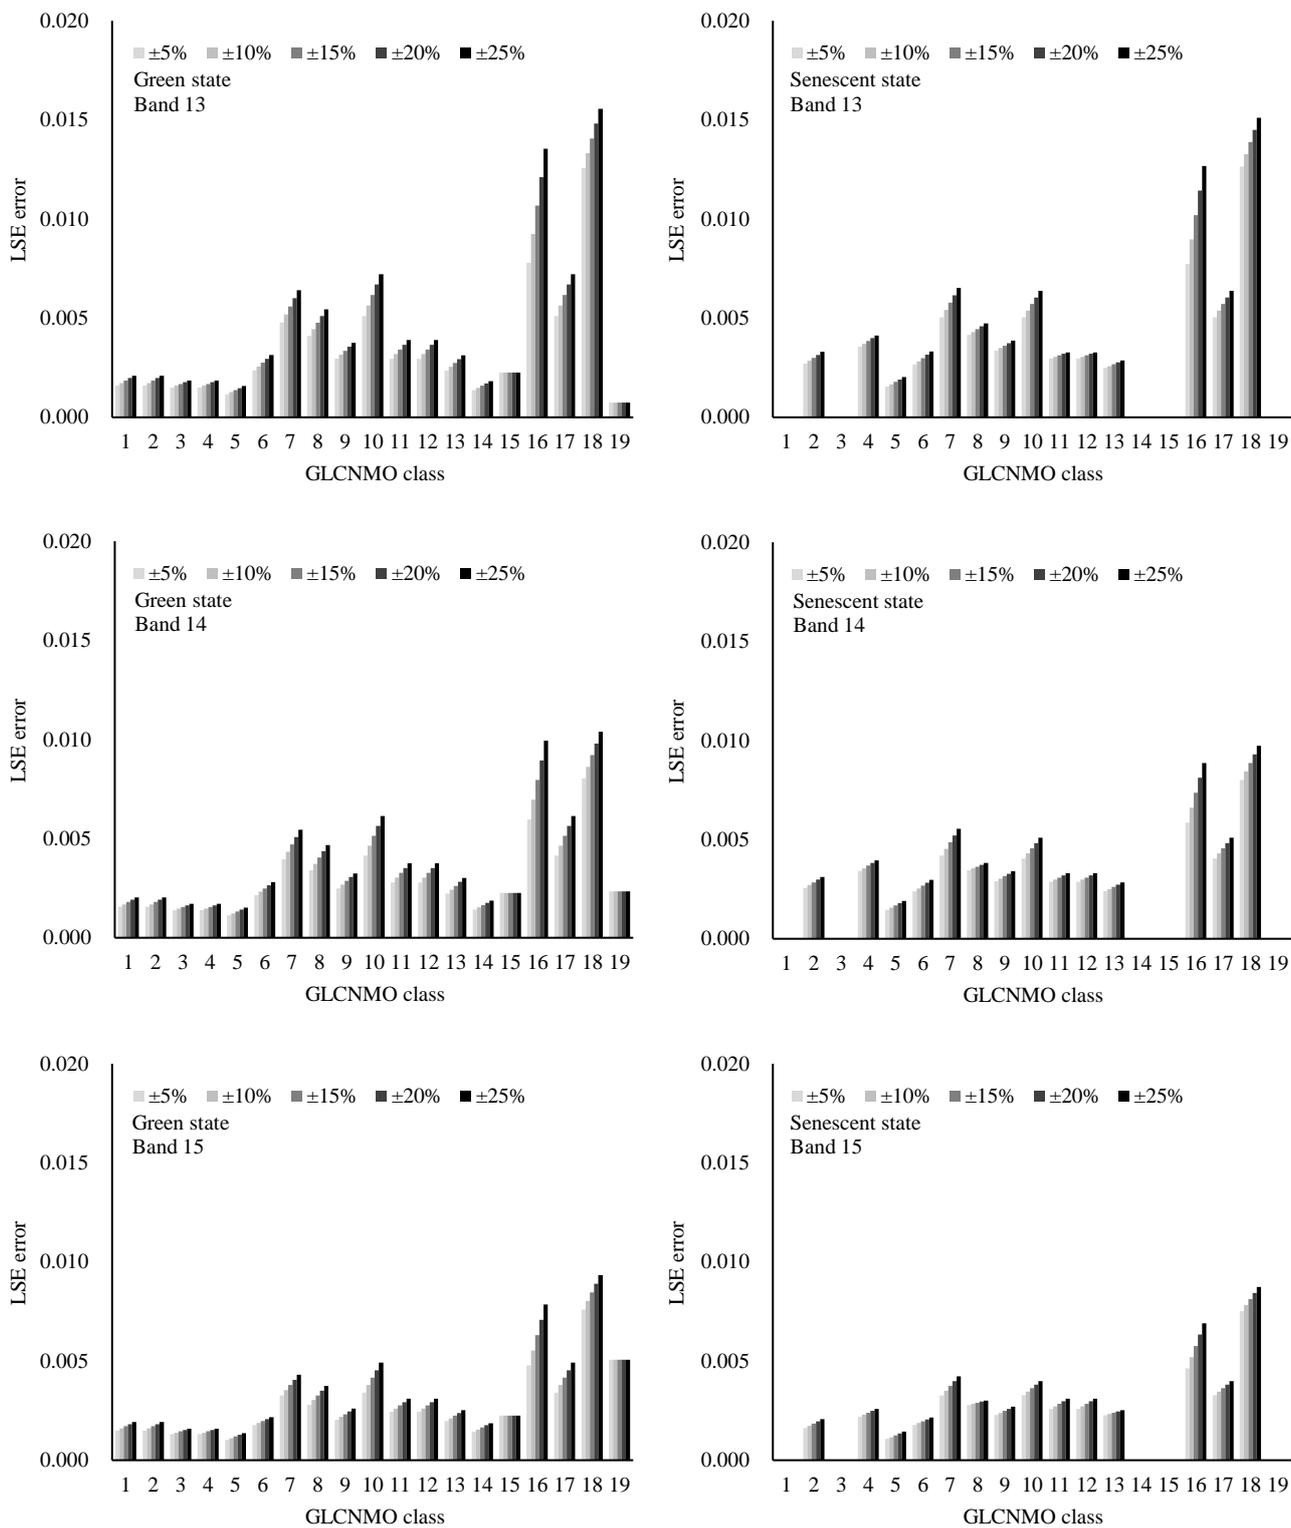

Fig. 6 The LSE error for each GLCNMO class and TIR band. The left figures show the LSE error in green state and the right figures show the LSE error in senescent state.
